Stochastic SIR Forecasting Showdown Part 1: Parameter Fitting

Dexter Barrows

21:48 27 February 2016

Setup

Now that we have established which methods we wish to evaluate ~~the efficacy of for epidemic forecasting~~, it is prudent to see how they perform when fitting parameters for a known epidemic model. We have already seen how they perform when fitting parameters for a model with a deterministic evolution process and observation noise, but a more realistic model will have both process and observation noise.

[margin note: epidemic forecasting]

To form such a model, we will take a deterministic SIR ODE model given by

[margin note: is this (SIR model def.) already stated/defined previously? or already known sufficiently to readers?]

$$\frac{dS}{dt} = -\beta SI$$
$$\frac{dI}{dt} = \beta SI - \gamma$$
$$\frac{dR}{dt} = \gamma I,$$

and add process noise by allowing β to embark on a geometric random walk given by

[margin note: follow?]

$$\beta_{t+1} = \exp\left(\log(\beta_t) + \eta(\log(\bar{\beta}) - \log(\beta_t)) + \epsilon_t\right).$$

We will take ϵ_t to be normally distributed with standard deviation ρ^2 such that $\epsilon_t \sim \mathcal{N}(0, \rho^2)$. The geometric attraction term constrains the random walk, the force of which is $\eta \in [0, 1]$. If we take $\eta = 0$ then the walk will be unconstrained; if we let $\eta = 1$ then all values of β_t will be independent from the previous value (and consequently all other values in the sequence).

Choosing an intermediate value of $\eta = 0.5$ gives us

[margin note: state Cor(beta(t),beta(t+1)) for a given value of eta and rho^2? (rho^2 slightly confusing since rho is often used as AR1 correlation.) Don't know if we've worked this out before or not.]
and corresponding density plot
Consider being slightly more formal, i.e. putting these plots in as a (float) figure with 2 sub-figures.

We see a density plot similar in shape to the desired density, and the geometric random walk

displays dependence on previous values.

We arrive at a mean of

```
## [1] 0.0006922973
```

put these in text, suitably rounded (document needs to look slightly less like a tech report and slightly more like a paper).
How do these values relate to the theoretical expectations?

and standard deviation of

```
## [1] 0.0003993207
```

Note that when $\eta \in (0,1)$, we have an autoregressive process of order 1 on the logarithmic scale of the form

$$X_{t+1} = c + \rho X_t + \epsilon_t$$

where ϵ_t is normally distributed noise with mean 0 and standard deviation σ_E. This process has a theoretical expected mean of $\mu = c/(1 - \rho)$ and variance $\sigma = \sigma_E^2/(1 - \rho^2)$. For the resulting log-normal distribution these yield a mean of

```
## [1] 0.0006798891
```

OK, I asked about this on the previous page, but I think you should move it up -- most sophisticated readers will expect that you'll jump straight to this, and may get grumpy if they don't see it right away/have to wait a half page to get there

and standard deviation

```
## [1] 0.0004458293
```

Which are very close to the experimentally determined values.   which are ... ?

If we take the full stochastic SIR system and evolve it using an Euler stepping scheme with a step size of $h = 1/7$, for 1 step per day, we obtain the following plot

explain that you need to use Euler, not something fancier such as Runge-Kutta, because stochasticity will screw up such stepping schemes. Not sure whether what you're solving here can be reduced to a closed-form *continuous-time* stochastic system, or whether you should just admit that you're using a discrete-time model here. (Could make the broader argument that modeling epidemic systems in more detail is questionable since there are many processes that occur at a finer time scale (diurnal, weekly cycles etc.) that are being completely neglected in any case.) Bottom line, you should say *something* to clarify that you recognize that this is a coarse approximation.

3
Here the solid line is a single random trajectory, the dots show the data points obtained by adding in observation error defined as $\epsilon_{obvs} = \mathcal{N}(0, 10)$, and the grey ribbon is centre 95th quantile from 100 random trajectories. See previous points about figures in-line vs. in \begin{figure}/\end{figure}

Calibrating Samples

might want to give a little more context here, i.e. point out that in general the effective computational cost of a method will depend on how many draws will be required to get a result of a given accuracy, multiplied by the computational cost per draw -- e.g. HMCMC compared to other MCMC methods costs more per draw but draws are more independent. Possibly also cf. variance-reduction methods for Monte Carlo computation in general, i.e. picking quasi-regular (Sobol) sequences rather than random seq

In order to compare HMCMC and IF2 we need to set up a fair and theoretically justified way to select the number of samples to draw for the HMCMC iterations and the number of particles to use for IF2. We assume that we are working with a problem that has an unknown real solution, so we use the Monte Carlo Standard Error (MCSE).

Suppose we are using a Monte-Carlo based method to obtain an estimate $\hat{\mu}_n$ for a quantity μ, where n is the number of samples. Then the Law of Large Numbers says that $\hat{\mu}_n \to \mu$ as $n \to \infty$. Further, the Central Limit Theorem says that the error $\hat{\mu}_n - \mu$ should shrink with number of samples such that $\sqrt{n}(\hat{\mu}_n - \mu) \to \mathcal{N}(0, \sigma^2)$ as $n \to \infty$, where σ^2 is the variance of the samples drawn.

We of course do not know μ, but the above allows us to obtain an estimate $\hat{\sigma}_n$ for σ given a number of samples n as

don't necessarily think you should worry about, but you're being loose here - do you need to specify what kind of limit/convergence (convergence in distribution, in probability, in mean) ?

$$\hat{\sigma}_n = \sqrt{\frac{1}{n} \sum_{i=1}^{n} (X_i - \hat{\mu})}$$

4

which is known as the Monte Carlo Standard Error.

We can modify this formula to account for multiple variables by replacing the single variance measure sum by

, potentially correlated, (margin annotation)

$$\Theta^* V(\Theta^*)^T$$

where Θ^* is a row vector containing the reciprocals of the means of the parameters of interest, and V is the variance-covariance matrix with respect to the same parameters. This in effect scales the variances with respect to their magnitudes and accounts for covariation between parameters in one fell swoop. We also divide by the number of parameters, yielding

(cute) (margin annotation)

$$\hat{\sigma}_n = \sqrt{\frac{1}{n}\frac{1}{P}\Theta^* V(\Theta^*)^T}$$

where P is the number of particles.

note that this is an average variation across parameters (different parameters x methods might give some variation) (margin annotation)

The goal here is to then pick the number of HMCMC samples and IF2 particles to yield similar MCSE values. To do this we picked a combination of parameters for RStan that yielded decent results when applied to the stochastic SIR model specified above, calculated the resulting mean MCSE across several model fits, and isolated the expected number of IF2 particles needed to obtain the same value. This was used as a starting value to "titrate" the IF2 iterations to the same point.

The resulting values were 1000 HMCMC warm-up iterations with 1000 samples drawn post-warm-up, and 2500 IF2 particles sent through 50 passes, each method giving an approximate MCSE of 0.0065.

possibly comment on approximate computational costs of these two methods? (interesting to separate out by costs, draws required, overall) (margin annotation)

IF2 Fitting

Now we will use an implementation of the IF2 algorithm to attempt to fit the stochastic SIR model to the previous data. The goal here is just parameter inference, but since IF2 works by applying a series ~~on~~ particle filters we essentially get the average system state estimates for a very small additional computational cost. Hence, we will will also look at that estimated behaviour in addition ~~the~~ the parameter estimates.

possibly set as \texttt{Rcpp} (and/or define \code{} macro so you can decide later) (margin annotation)

The code used here is a mix of R and C++ implemented using RCpp. The fitting was undertaken using 2500 particles with 50 IF2 passes and a cooling schedule given by a reduction in particle spread determined by 0.975^P, where p is the pass number starting with 0.

how did you choose cooling rate? previously discussed? how does this compare with typical practices of King, Ionides? (margin annotation)

The MLE parameter estimates, taken to be the mean of the particle swarm values after the final pass, were

```
##        R0         r        I0     sigma       eta      berr
## 3.2831681 0.1029662 6.6489590 8.8152251 0.8822255 0.2615560
```

giving a relative error of

```
##         R0          r         I0      sigma        eta       berr
##   0.09438935 0.02966181 0.32979181 -0.11847749 0.76445101 -0.47688790
```

From last IF2 particle filtering iteration, the mean state values from the particle swarm at each time step are shown with the true underlying state and data in the plot below

where the solid line shows the true states, the points are the data, and the dashed line shows the state estimates from the last IF2 filtering pass.

IF2 convergence plots

Since IF2 is an iterative algorithm where each pass through he data is expected to push the parameter estimates towards the MLE, we can see the evolution of these estimates as a function of the pass number. Plots showing evolution of the mean estimates are shown below for the six most critical parameters.
6
The horizontal axis shows the IF2 pass number. The solid black lines show the evolution of the ML estimates, the solid grey lines show the true value, and the dashed grey lines show the mean parameter estimates from the particle swarm after the final pass.

Similarly, we can look at the evolution of the standard deviations of the parameter estimates from the particle swarm as a function of the pass number, shown below.

The horizontal axis shows the IF2 pass number and the solid black lines show the evolution of the standard deviations of the particle swarm values. As expected there is a downward trend in all plots, with a very strong trend in all but two of them.

again, explain expected patterns. I initially thought these should be flattening more but realized that they should (??) actually all converge asymptotically to zero -- right?

IF2 Densities

Of diagnostic importance are the densities of the parameter estimates given by the final parameter swarm. These are shown below.

explain why -- what patterns would cause us to worry?
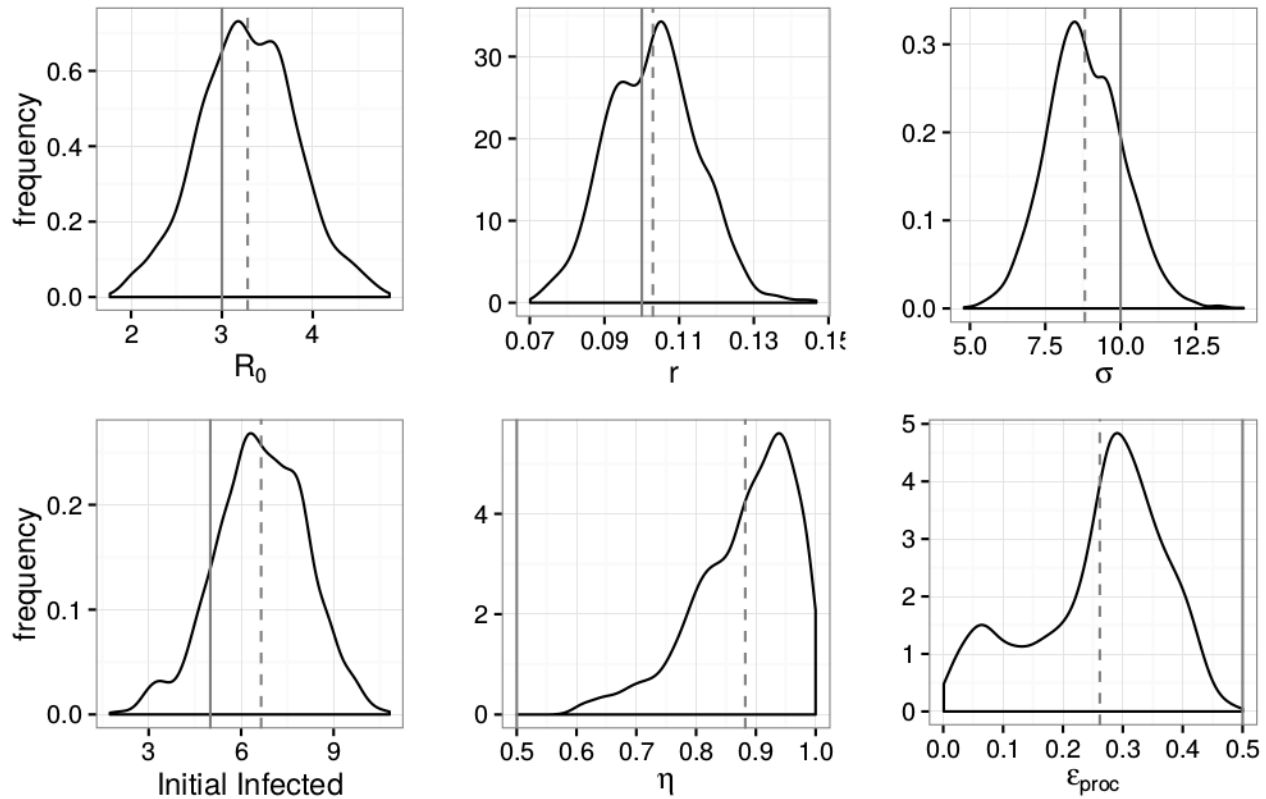

As before, the solid grey lines show the true parameter values and the dashed grey lines show the density means. It is worth noting that the IF2 parameters chosen were in part chosen so as to not artificially narrow these densities; a more aggressive cooling schedule and/or an increased number of passes would have resulted in much narrower densities, and indeed have the potential to collapse them to point estimates.

can you remind me/us why you *don't* want these to collapse to point estimates?

HMC Fitting

We can use the Hamiltonian Monte Carlo algorithm implemented in the `Rstan` package to fit the stochastic SIR model as above. This was done with a single HMC chain of 2000 iterations with 1000 of those being warm-up iterations.   perhaps use the term "burn-in" for connection with literature

The MLE parameter estimates, taken to be the means of the samples in the chain were

```
##         R0          r         I0      sigma        eta       berr
## 3.31518747 0.09992437 6.64178678 8.49567589 0.45861340 0.16024089
```
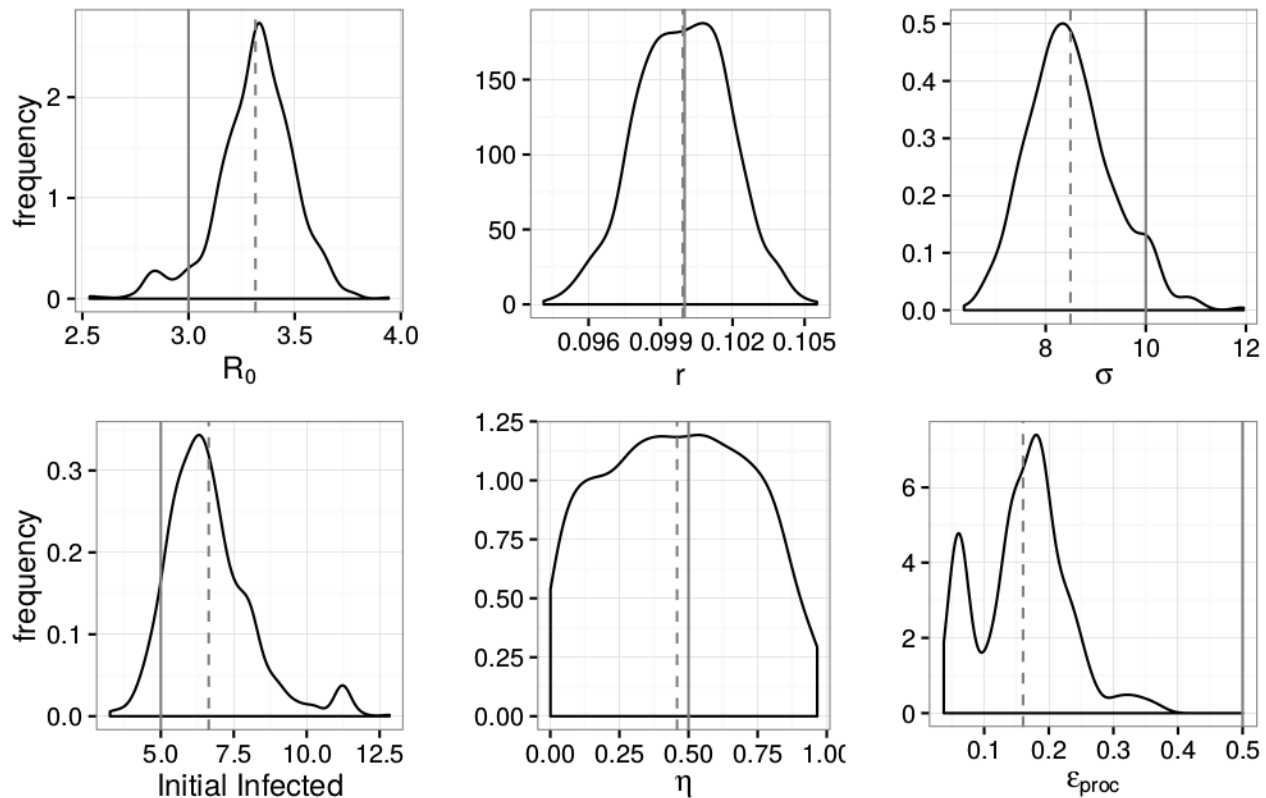

giving a relative error of

```
##           R0              r            I0         sigma            eta
##   0.1050624905 -0.0007562921   0.3283573555 -0.1504324110 -0.0827732048
##         berr
## -0.6795182175
```

9

HMC Densities

The densities produced by Stan's HMC implementation are shown below:

As before the solid grey lines show the true values and the dashed grey lines show the density means.

It is worth noting that the densities shown here represent a "true" MLE density estimate in that they represent HMC's attempt to directly sample from the parameter space according to the likelihood surface, unlike IF2 which is in theory only trying to get a ML point estimate. Hence, these densities are potentially more robust than those produced by the IF2 implementation. *Clarify, I think? Do you want to comment on Bayes vs frequentist paradigm here? (In practice, the two paradigms often get quite muddled/mixed in dynamic forecasting problems ...)*

HMC Bootstrapping

need to give a little more detail about how this works (i.e. sample from posterior of vector of latent betas [have to sample all at once as autocorrelated] and posterior of I(0) gives reconstructed S/I/R. Related, although slightly tangentially, to "susceptible reconstruction" approaches (Fine & Clarkson, Bobashev et al.)

Unlike particle particle-filtering-based approaches, HMC does not produce state estimates as a by-product of parameter fitting, but we can use information about the stochastic nodes related to the noise in the β geometric random walk to reconstruct state estimates. The results of 100 bootstrap trajectories is shown below: *explain how? (i.e. math formulae, not computer code)*

*couldn't it, as long as we retained information about latent variables? (I guess the point here is that we're not keeping track of states as latent variables. But this is rather unusual -- most MCMC reconstructions would implement process error directly in the state evolution (not incorporated as autoregressive variation in beta), and as a result *would* give direct state estimates. Perhaps worth discussing this further earlier/in set-up/prologue.*
As before the solid line shows the true states, the dots show the data, the dotted line shows the average system behaviour, the dashed line shows the bootstrap mean, and the grey ribbon shows the centre 95th quantile of the bootstrap trajectories.

Multi-trajectory Parameter Estimation

Here we fit the stochastic SIR model to 200 random independent trajectories using each method and examine the density of the estimates.

First, the average running time over all trajectories for IF2 was

```
## [1] 45.48117
```

And the average running time for the RStan HMCMC fits was

```
## [1] 257.3656
```

~~It is worth noting that~~ the IF2 implementation is almost 6x the speed of the RStan HMCMC implementation, but we are obtaining less information. This will become important in the next section. Should this be integrated with previous discussion about MCSE/effective sample size?

The density plots for the centre 95% quantiles of IF2 parameters fits are shown below.

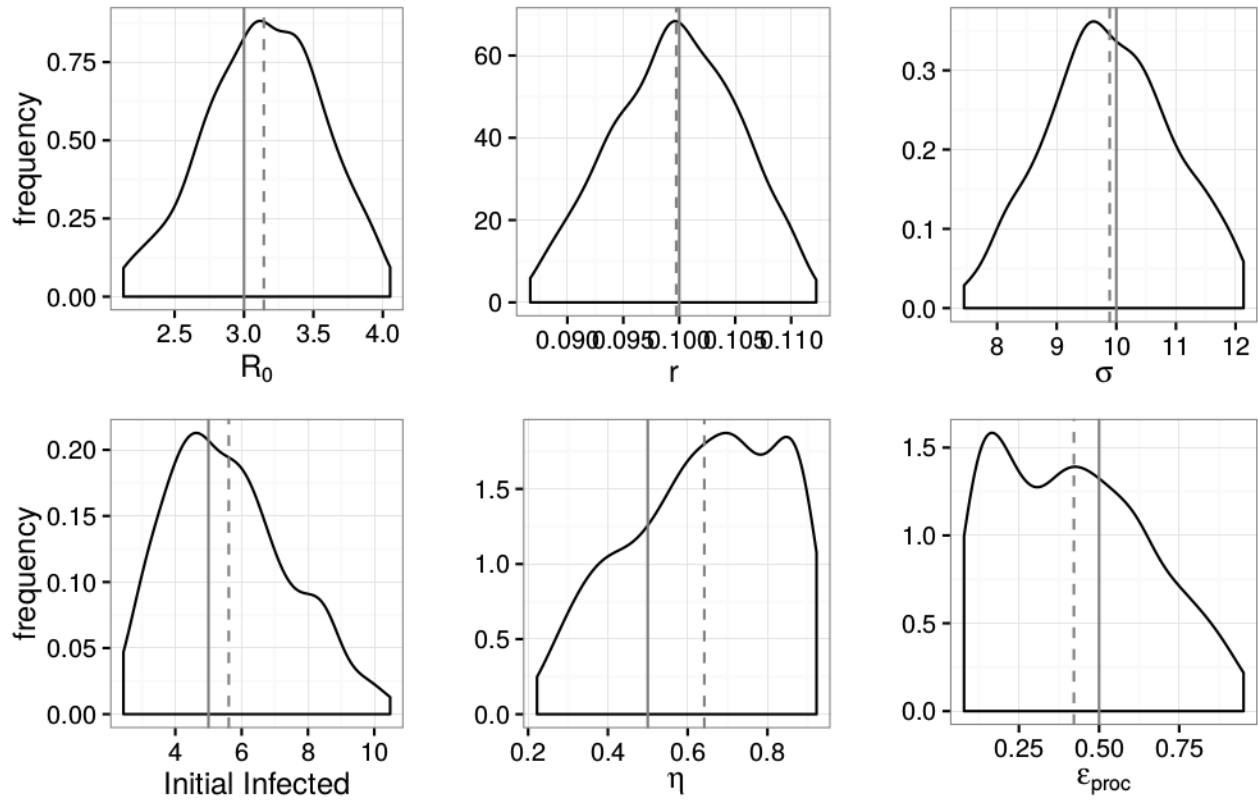

Here the solid grey lines are the true values, and the dashed grey lines are the density means.

Similarly, the density plots for the centre 95% quantiles of RStan HMCMC parameters fits are shown below.
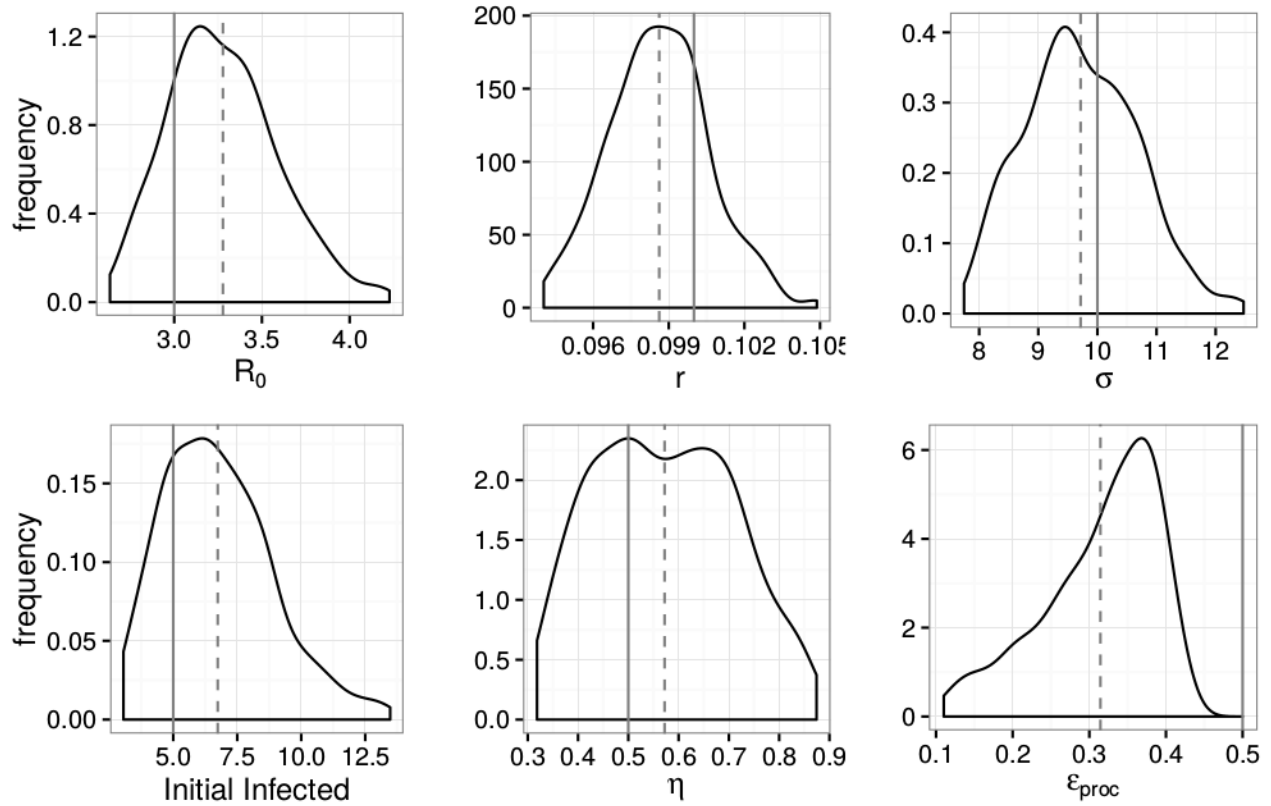

As before, the solid grey lines are the true values, and the dashed grey lines are the density means.

We can overlay the densities to compare average behaviour, shown in the following plot.

Is it worth combining any of these plots, to prevent reader fatigue? (Have to trade off (1) desire of readers to follow up everything, wish to give complete story vs. reader fatigue (2) many simple plots vs few, possibly too complex, plots)
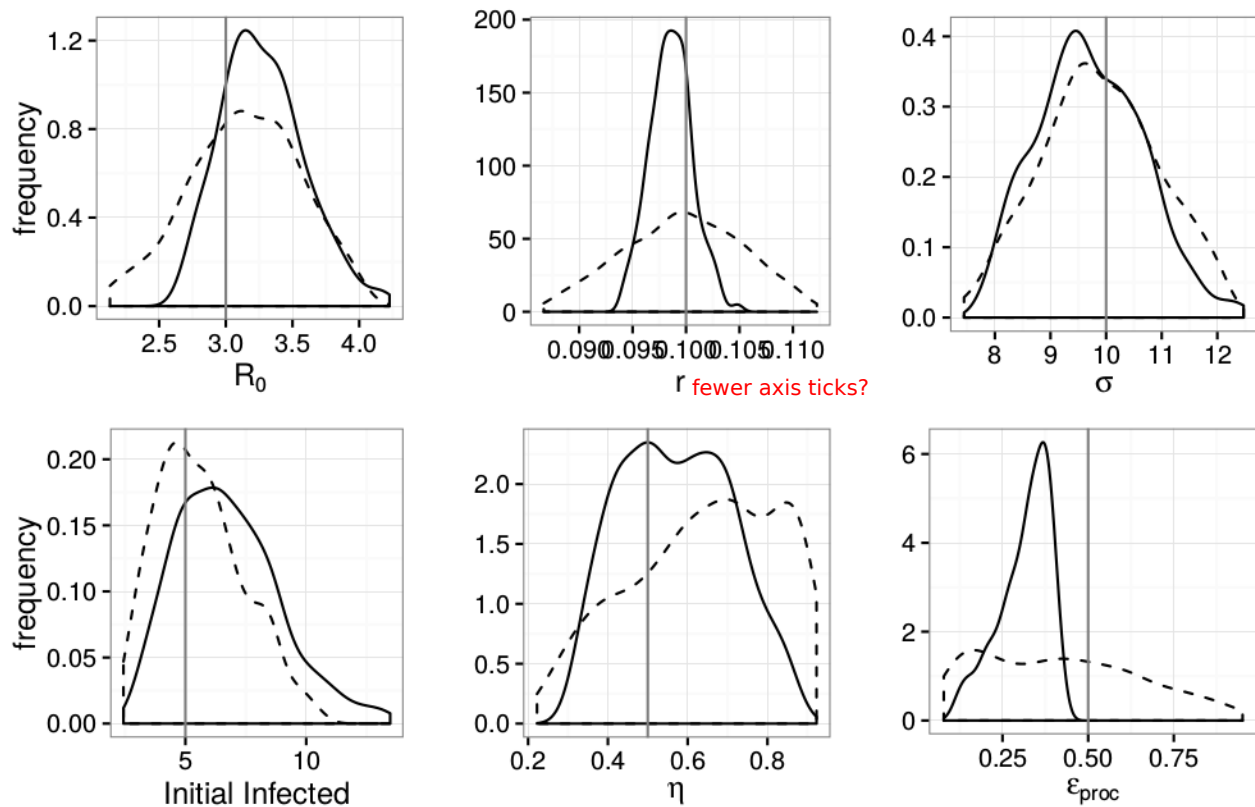

Here the HMCMC densities are the solid lines and the IF2 densities are the dashed lines. The densities by and large display similar coverage, with the IF2 densities for r and ε_{proc} showing slightly wider coverage than the HMCMC densities for the same parameters.

see prev note about subscripts

have you defined coverage? Do you want to indicate 95% tails? Can we (at least roughly) estimate coverage from these plots? (Do we actually get coverage from this plot, or would we have to add yet another nested layer [repeat bootstrap computations and/or HMCMC fits] in order to know the accuracy of the CI calculations?
